ABSTRACT

As part of the remedial investigation and feasibility study being conducted at the Army Materials Technology Laboratory in Watertown, Massachusetts, Arthur D. Little, Inc., conducted a program of physical characterization and sampling of the site. The geology and hydrology of the site was summarized using data from 17 soil borings, one of which was cored 15 feet into bedrock, physical testing of soil samples, water level measurements and determination of in situ hydraulic conductivity from 16 monitor wells, a seismic refraction survey to determine depth to bedrock and stratigraphic variation, and two borehole geophysical surveys.

Bedrock at the site consists of the Pennsylvanian Cambridge Argillite, a dense, finely laminated siltstone. The siltstone is overlain by a basal, bouldery till with a gray green, silt-rich sandy to gravelly matrix. Laying on top of the till is a laminated, silty sand found across the site, which is composed of moderately well sorted, very fine to fine-grained sand, with a clayey-silty matrix. Overlying the silty sand is a texturally variable layer of medium to coarse-grained sand and gravel, which is not found over the entire site. It is absent in the northwest corner of the site and grades to a gravelly sand eastward. The coarser sand-gravel unit is generally overlain by fill of disturbed gravel with exotic debris (concrete, brick, ceramic, etc.).

Surface run-off across the site is to the south, toward the Charles River, which is within 100-400 feet of the site. Groundwater flow, estimated by water level data, is to the south. The gradient averages 0.03 across the site, but in the southeast corner it decreases to 0.003. In situ hydraulic conductivities (k) were determined by falling head and rising head tests. For the silty sand, k ranges from 7.06 x 10^{-4} to 1.30 x 10^{-2} cm/sec and averages 6.4 x 10^{-3} cm/sec. For the coarser sandy gravel, k ranges from 4.24 x 10^{-3} to 3.30 x 10^{-2} cm/sec, averaging 2.7 x 10^{-2} cm/sec. From a packed pressure test, k for the argillite was found to average 4.1 x 10^{-7} m/sec. The flow rate through the site was calculated to be 0.016 m³/sec (98 gpm). Estimated flow velocities vary from 6.4 x 10^{-4} cm/sec (142 m/yr) to 4.5 x 10^{-5} cm/sec (14.2 m/yr) where 4.5 x 10^{-4} cm/sec is most representative.

1.0 BACKGROUND

The U.S. Army Toxic and Hazardous Materials Agency (USATHAMA) has contracted with the Department of Energy-Idaho Operations Office to conduct a Remedial Investigation and Feasibility Study (RI/FS) at the Army Materials Technology Laboratory (AMTL) in Watertown, Massachusetts. The objective of the RI/FS is to characterize the extent to which hazardous materials may have contaminated the environment and to evaluate appropriate remedial alternatives. To complete the RI/FS, the Department of Energy, through their contractor, EG&G Idaho, Inc., has subcontracted Arthur D. Little, Inc., to perform physical characterization and sampling of the site. Specific tasks assigned to Arthur D. Little, Inc., included:

- (a) Obtaining all permits, approvals, and licenses required by federal, state, local, USATHAMA, and AMTL authorities to perform the requested services.
- (b) Performing a seismic refraction survey to map depth to bedrock at the AMTL.
- (c) Drilling of three holes 10 feet into bedrock and installation of monitor wells.
- (d) Drilling of 14 holes approximately ten feet into the water table and installation of monitor wells.
- (e) Collection of soil samples at 5-foot intervals.
- (f) Monitoring of drill cuttings, all samples and all wastes for organic vapors, flammability and radioactivity.
- (g) Development of all wells completed.
- (h) Hydraulic testing of all wells completed.
- (i) Geophysical borehole logging of the three holes drilled into bedrock.
- (j) Collection of soil samples for chemical analysis (one per hole, two in MW-3).
- (k) Physical testing of approximately 20% of the soil samples collected for Atterberg limits, bulk density, specific gravity, porosity, hydraulic conductivity, and sieve grain size distribution.
- (1) Collection of water samples from each completed well for chemical analysis.

- (m) Measurement of water levels in all completed wells and at one location on the Charles River.
- (n) Surveying locations and elevation of all completed wells.
- (o) Entering all appropriate data into the USATHAMA Data Management System.
- (p) Documenting all data in a final report.

All of the above tasks were successfully accomplished except for modifications in the core holes. Hole CO3 was cored 15 feet into bedrock and abandoned after hydraulic testing, on request of EG&G Idaho, Inc. Hole CO2 was prematurely terminated because of high volatile organic and explosivity measurements, on the advice of Arthur D. Little, Inc., with concurrence by EG&G, Idaho. Hole CO3 was terminated in the basal till rather than cored into bedrock at EG&G Idaho's request.

Prior to commencing work at the AMTL, Arthur D. Little, Inc., prepared a Health and Safety Plan, a Quality Control Plan and a Sampling Plan. These plans were approved by EG&G Idaho, Inc., and detailed our procedures for site safety, operating procedures and quality objectives for site activities, and sampling procedures. During the entire period of the program, quality objectives and performance were audited by Arthur D. Little's Quality Control Manager and, during activity on site, safety procedures were monitored by Arthur D. Little's Health and Safety Manager.

2.0 REGIONAL GEOLOGY

2.1 Site Location

The Army Materials Technology Laboratory is located in Watertown, Massachusetts, about six miles west of Boston (Figure 1). The facility currently occupies approximately 35 acres on the north bank of the Charles River and includes ten major structures used for research and development, testing, and manufacturing.

2.2 Bedrock Geology

The AMTL facility is located within the north central portion of the Boston Basin, a topographic and structural basin bounded on the north and northwest by the North Boundary Thrust Fault, on the west by normal faulting and to the south by the Blue Hills and Ponkapoag Thrust Faults (Figure 2). To the southwest, intricate thrusting and tight, east plunging folds complicate the margin. The eastern margin of the basin is beneath Massachusetts Bay (Billings, 1976). Topographically the basin is bounded by low hills to the north, west, and south.

The basin is a structurally bounded depression in Precambrian basement filled with younger Mississippian and Pennsylvanian rocks (LaForge, 1932; Billings, 1976 and Kaye, 1980). At the southwest margin of the basin, the Precambrian basement outcrops in the cores of northeast plunging anticlines. To the south, between the Ponkapoag and Blue Hills Thrust Faults, the basin is intruded by the peralkaline Blue Hills Complex of Cambrian-Devorian age. The Blue Hills complex includes the Quincy Granite and other felsic intrusions. In the southwest portion of the basin, altered felsic and basaltic volcanics of the Mississippian Mattapan Complex are exposed. Volcanics of similar composition assigned to the Mississippian Lynn Complex are exposed north of the Northern Boundary Fault. Both volcanic complexes crosscut the Precambrian basement and are included as clasts in the Pennsylvanian Boston Bay Group (LaForge, 1932).

The Boston Bay Group consists of two formations, the lower Roxbury conglomerate and the upper Cambridge Argillite. LaForge (1932) subdivided the Roxbury Congolomerate into three members, the Squantum, Dorchester, and Brookline members. In general, the Roxbury Conglomerate outcrops south of the Charles River over the southern portion of the basin, and the Cambridge Argillite outcrops north of the Charles River.

The Cambridge Argillite is typically a varved or rhythmically layered, indurated siltstone. Beds range in thickness from 0.1 to 8 cm, and vary from dark gray clay to silt-rich layers to light gray very fine to fine-grained sand layers. Graded beds, cross beds, ripple marks, and slump structures are observed.

FIGURE 1. LOCATION OF ARMY MATERIALS TECHNOLOGY LABORATORY, WATERTOWN, MASSACHUSETTS.

FIGURE 2. GENERAL GEOLOGY OF THE BOSTON BASIN. (After Billings, 1976)

2.3 Structural Geology

The internal structure of the Boston Basin consists of a series of broad folds, plunging gently to the northeast or east (Billings, 1976). The AMTL facility is located on the axis of the Charles River Syncline (Figure 2). Most of the fault zones in the basin, including the bounding thrust faults, trend east-northeast. The only major exceptions to this are the Stony Brook Fault and an unnamed fault at the southwest margin of the basin, which are both normal faults and trend north-northeast and north-northwest, respectively. The Stony Brook Fault is mapped from Fresh Pond, approximately two miles east of the AMTL, south-southwest for approximately 20 miles.

2.4 Quarternary Geology

Numerous glacial advances and retreats in the vicinity of the Boston basin from 2 million years to 12,000 years ago have left a complex stratigraphic sequence of till, clay, and gravel. In general, the Quaternary aged deposits in the Boston Basin consist of (in ascending order) a basal till overlaying the bedrock, 0 to 70 feet thick, a marine clay, 0 to 60 feet thick, and outwash deposits of sand and gravel, 0 to 50 feet thick. General properties of the basal till and outwash deposits for the Boston area are summarized in Table 1.

TABLE 1. GENERAL PROPERTIES OF BASAL TILL AND OUTWASH DEPOSITS IN THE BOSTON AREA (After Hatheway, 1982)

Outwash	Gap-graded/poorly sorted semi-homogeneous	Few to none	0-10	0-5	Nil	Loose - moderately compact	Subangular-rounded	Non-plastic	Non-plastic	0-20+	approx. 0	25-45	Normal to underconsolidated	10^{-2} to 10^{-5}
<u>Lodgement (Basal) Till</u>	Well graded; very heterogeneous	Many, including erratics	20-60	5-30	Governs engineering properties	Stiff - hard	Angular-subangular	15-30	0-20	20-200+	0-25	15-33	Overconsolidated	10^{-5} to 10^{-9}
<u>Characteristic</u>	Particle Size Gradation	Presence of Boulders	Percent (-) 200 Sieve	Percent (-) 0.02 mm	Effect of Fines	Relative Density	Particle Shape	Liquid Limit (%)	Plasticity Index	Standard Penetration (blows)	Cohesion (KN/m^2)	Friction Angle (°)	Consolidation Ratio	Permeability (in situ) (cm/sec)

3.0 SITE GEOLOGY

3.1 Site Location

The Army Materials Technology Laboratory is located in Watertown, Massachusetts, on the north bank of the Charles River (Figure 1.) The site and surrounding area is generally flat, decreasing in elevation (National Geodetic Vertical Datum, 1929) from approximately 36 feet at the north to approximately 2.4 feet river elevation at the south (Figure 3). Almost the entire AMTL facility is situated on a low bluff, approximately 20 to 28 feet.

The present AMTL facility covers approximately 47.5 acres bounded by Arsenal Street on the north, North Beacon Street to the south, commercial property to the west, and a park to the east. The 55 acres immediately to the east of the present facility were part of the AMTL prior to 1968. This area now accommodates a park, a condominium complex, and retail stores (the Arsenal Mall). North of the facility there are commercial and light industrial properties. To the south, between North Beacon Street and the Charles River, are approximately 11 acres of former AMTL property which now accommodate a marina and park.

There are no known streams or natural drainages emptying to the Charles River in the vicinity of the AMTL. All surface run-off is collected in the storm drain network and discharged to the river.

The locations of the holes bored at AMTL during this study are shown in Figure 4. Two geologic cross sections, oriented approximately northwest-southeast are presented in Figures 5 and 6. The boring logs are found in Appendix A.

3.2 Bedrock Geology

The AMTL facility is underlain by siltstone of the Pennsylvanian Cambridge Argillite. The siltstone was encountered at a depth of 61.5 feet in hole CO1, at the northwest corner of the facility. At this location, the siltstone was very finely laminated with dark bluish gray silt to clay beds and light bluish gray, very fine to fine grained sandy graded beds.

Occasional tensional fractures of approximately one to two inches in length were filled with quartz. Only a few fractures parallel to bedding and most cutting bedding contained thin films of red brown iron oxide which suggests a pre-existing open network of fractures which allowed circulating groundwater to oxidize, transport and redeposit iron. Most fractures were parallel to bedding (about 30° to 45° to core axis) and may have resulted from drilling since they contain no iron oxide film.

M07

SECTION M10

GEOLOGIC CROSS

5.

FIGURE

11

Observation of joints in a nearby outcrop, approximately $1\frac{1}{4}$ miles southwest of the facility, indicates three broad orientations:

- (a) parallel to bedding, oriented approximately east-west, dipping about 20-30° south;
- (b) a dominant set, oriented north-northeast, dipping nearly vertical; and
- (c) parallel to sheer zones, oriented east-northeast.

The north-northeast joint orientation is also that generally followed by felsic dikes in the Boston Basin (striking N15-45°E, dipping 60-90°) and the Stony Brook Fault.

3.3 Quaternary Geology

Based on drilling (Figures 5 and 6) and a seismic refraction survey, approximately 45 to 120 feet of Quaternary sediments have been deposited over the Cambridge Argillite bedrock at the AMTL. While the precise stratigraphy varies from hole to hole, a generalized ascending sequence consists of a basal till of fairly cohesive, silt rich gravel; a moderate to well sorted olive brown, silty, fine-grained sand; a medium to coarse-grained brown sand, locally grading to about 30% gravel; locally a sandy peat; and finally, fill material or disturbed sand and gravel.

3.3.1 Basal Till

The basal till was encountered in only two holes on site, CO1 and CO3 and penetrated only in CO1. In CO1, the till was only six feet thick and consisted of round to subround cobbles of granite and felsic volcanics and subangular fragments of argillite. No split spoon samples were obtained in the till in CO1 because of refusal, so the composition of the matrix is not known. In CO3, the till consisted of a gray green silt rich gravel with angular decomposed rock fragments and medium to coarse-grained sand. While the exact thickness of the till is not known at the location of CO3, based on the depth of bedrock estimated from the seismic refraction profile, it would appear to be approximately 25 feet thick. In drilling previously completed to gather geotechnical data for foundation design, the till was encountered in a hole approximately 200 feet west of MO3 at a depth of The till was described as a dense brown clayey silty sand 76 feet. with gravel.

3.3.2 Silty Sand

The silty sand is found across the site and is usually comprised of a moderate to well sorted, very fine to fine-grained sand, with a silty-clayey matrix, commonly laminated. Its thickness ranges from approximately 10 feet in CO3 to 50 feet in CO1. It does not appear to be encountered in MO7 or MO8 and is thinnest in CO3, so it

may pinch out eastward. Since it was penetrated only in these two holes, it is not possible to make any conclusions regarding systemic variations in thickness. The silty sand probably represents a distal outwash deposit in a lacustrine environment.

3.3.3 Medium to Coarse Sand/Gravel

The medium to coarse-grained sand/gravel unit is highly variable in textural composition and is not found over the entire site. Where encountered, it lays above the silty sand and is overlain by fill and disturbed sands and gravels. It was not encountered in the northwest corner of the facility (Figure 5) and seems to grade from a medium to coarse-grain, well sorted, brown sand in the west portion of the facility to a yellowish brown, poorly sorted, gravel (30-40% pebbles and cobbles) with a poorly sorted, fine to coarse-grained sand matrix to the east. It ranges in thickness from absent to more than 35 feet, but averages approximately 10 feet. It is sometimes difficult to distinguish the gravel from disturbed or fill material, but in most cases the fill gravels were grayish brown and contained exotic debris such as brick, slag, concrete, and ceramics. The sand/gravel deposits probably represent fluvial (glacial meltwater) deposits.

3.3.4 Peat

In CO3 at the southeast corner of the facility (Figure 6), a sequence of organic rich sand and sandy peat was encountered. This is the lowest portion of the AMTL (11.9 feet), about 9 to 10 feet above normal Charles River elevation. The sandy peat probably represents a flood plain wetland deposit and consisted of grayish brown woody plant fragments and silty fine sand. When exposed to air, the peat gave off a sulfurous odor and immediately oxidized to a black brown color. Peat was not encountered in M11 or M06, the other low elevation hole locations. Examination of the cross section of Figure 5 suggests that any peat that may have been deposited at that stratigraphic elevation would have been eroded by the deposition of the coarse sandy gravels which may represent a flood deposit.

3.3.5 Fill and Surficial Soils

Fill at the AMTL facility is variable in distribution and thickness but is generally less than 20 feet. Usually the fill consists of poorly sorted sandy gravel, grayish brown in color. It commonly contains exotic debris such as brick, slag, concrete, and ceramics which can be used to distinguish it from the underlying fluvial gravels.

The surficial soil at the AMTL is classified as Merrimac gravelly sand loam. It consists of 6 to 10 inches of dark brown gravelly sandy loam overlying 15 to 25 inches of yellow brown, friable gravelly sandy loam. The soil has been repeatedly disturbed during the history of the AMTL by various construction activities.

Depth from surface to bedrock was estimated across the site using three seismic refraction profiles (Figure 7). The results of these three profiles, shown in Figure 8, indicate a generally, gently undulating surface. The east-west profile shows a bedrock surface varying from 47 feet (below surface) at the northwest corner of the facility, falling off to about 110 feet and then rising to 90 feet at the northeast corner. The north-south profiles show a decrease in depth from 120 feet at the north to about 65 feet at the south. Based on the east-west seismic refraction profile bedrock at location CO1 was predicted at 57 feet. The actual depth was 61.5 feet indicating very good agreement. The two profiles at the southeast corner of the facility which show a bedrock surface rising toward the Charles River, show no evidence of the Charles Buried Valley which is reputed to border the south margin of the facility (Figure 9).

3.4 Hydrology

3.4.1 Surface Water

Surface water run-off and natural drainage at the AMTL has been greatly influenced by modifications made to the natural land surface by construction of various structures and paved areas such as roads and parking lots. Watertown, in the vicinity of the AMTL, is heavily developed. The nearest pond, Sawins Pond, is approximately 3,000 feet east of the AMTL. The Charles River, one of the primary drainages in the Metropolitan Boston area, borders the site to the south. There are no known streams or other natural drainages to the Charles River in the vicinity of the AMTL. Current surface drainage is dominantly to the storm sewer system which discharges into the river. Some natural run-off will follow topography toward the river. Natural recharge through seepage is probably quite minimal in the vicinity of the AMTL because of the number of structures and paved areas.

3.4.2 Groundwater

Characterization of groundwater hydraulics at the AMTL is based on 17 borings and 16 monitor wells installed at the site during May and June of 1988. Water level measurements were taken and in situ permeabilities measured by falling and rising head tests.

Based on water level measurements taken at all wells and the Charles River on July 13, 1988 (Table 2), groundwater contours were estimated (Figure 10). These contours indicate flow is generally to the south, toward the River. In the northeast corner of the site, flow is to the southeast initially and then swings around to the south. Using the contours shown in Figure 10, gradients were estimated. Across the west portion of the site, the gradient was 0.025 (south). At the north central portion of the site, the gradient was 0.03 (southeast) but to the south decreases to 0.003. At the east margin of the site, the gradient was 0.003 (south).

4.0 METHODOLOGY

4.1 Geotechnical Approach

As a preliminary step in conducting a remedial investigation and feasibility study, EG&G Idaho, Inc., completed a preliminary assessment/site inspection (PA/SI) at the facility (EG&G, 1988). The PA/SI consisted of (1) reviewing historical records and conducting interviews to determine past practices and their potential impact on the environment, (2) wipe sampling of building interiors for radionuclide monitoring, and (3) a shallow soil gas survey to identify areas of potential volatile organic contamination.

The PA/SI review of historical records and interviews revealed that because of past practices, the following contaminants might be present in soil or groundwater:

- (a) depleted uranium (DU);
- (b) chlorinated solvents;
- (c) a wide variety of toxic organic compounds used as reagents in organic synthesis and fiber epoxy composite manufacturing;
- (d) a wide variety of toxic inorganics such as lead, beryllium, cadmium, mercury, nickel, chromium, and cyanide; and
- (e) hydrocarbons including fuels, cutting, quenching, and heat transfer oils.

The shallow soil gas survey was conducted by Tracer Research Corporation (EG&G, 1988). Samples of soil gas were taken at depths of 1 to 20 feet with most samples in the range of 3 to 5 feet. The samples were analyzed in the field on a gas chromatograph with an electron capture detector for chloroform, 1,1,1-trichloroethane (TCA), carbon tetrachloride, trichloroethylene (TCE), and perchloroethylene (PCE), and on a gas chromatograph with a flame ionization detector for benzene, toluene, and xylene.

The soil gas survey revealed coincident TCA and benzene contamination along the edge of the AMTL at the northwest corner of Building 311. The highest concentrations were 425 mg/l TCA and 24 mg/l benzene in the vicinity of M13. Other areas of low level benzene contamination <1 mg/l are found in the center of the facility near M03 and along the southeast margin between M11 and M06.

Based on the information obtained in the PA/SI, monitor well and core hole locations were selected by EG&G. The locations selected are shown in Figure 4, and the rationale for selecting each location is summarized in Table 4.

TABLE 4. SELECTION CRITERIA FOR MONITOR WELL LOCATIONS (EG&G IDAHO, INC.)

Well No.	<u>Rationale</u>
M01	Downgradient perimeter
M02	Downgradient perimeter, downgradient of analytical chemistry lab (292)
м03	Low concentration benzene contamination
M04	Possible fill area, cinder and ash from coal fired plant
M05	Downgradient of bulk fuel oil tanks documented spills
MO6	Downgradient perimeter
M07	Eastern perimeter
M08	Eastern perimeter
M09	Upgradient perimeter, underground fuel tanks, DU facility
M10	Upgradient perimeter
M13	Upgradient perimeter, coincident TCA and benzene contamination
M14	Downgradient of waste storage area
C01 C02 C03	Core holes situated to develop information on depth to and nature of bedrock across site

4.2 <u>Drilling Techniques</u>

Sixteen holes were augered in overburden and one hole cored into bedrock and abandoned. All drilling and well construction was performed by GZA Drilling, Inc., of Brockton, Massachusetts. Holes were drilled with a CME 75 or CME 55 drill rig using an 8½" hollow stem auger to a completion depth of approximately 10 feet below the water table. Soil samples for logging purposes were obtained every 5 feet using a 2 inch I.D. split spoon. Soil samples for chemical analysis and physical testing were taken at specified depths.

The hole cored into bedrock, CO1, was drilled by advancing 10 inch I.D. hollow stem augers to the water table, spinning 8 inch casing to refusal (top of basal till), and coring through the till, casing with 4 inch casing and coring 15 feet into bedrock using diamond surface set bit with a 3 inch core barrel. Water was used during coring and recirculated from a settling tank. Because of the low hydraulic conductivity measured for the bedrock during a pressure packer test, it was decided by EG&G Idaho, Inc., upon Arthur D. Little's advice, not to install a monitor well and CO1 was abandoned. All casing was removed and the hole was grouted to surface using cement.

The drill rigs and all equipment were steam cleaned at GZA Drilling's Brockton shop prior to arrival on site, upon arrival at the site, after completion of each hole, and prior to leaving the site. A steam cleaning area adjacent to the hydrant used as a water source was set up using heavy mil plastic, forming a lip to contain the water. Water was pumped into 55 gallon drums and labeled "steam cleaning water" for later disposal.

4.3 Borehole Logging

Boreholes were logged by geologists from Weston Geophysical Corporation under the supervision of Arthur D. Little, Inc. Required information was noted in ink on the boring logs and included depth, sample intervals, recovery, blows per 6 inch in advance of the split spoon, and a geologic description of cuttings and split spoon samples. Soils were described as to color using the Geological Society of America Rock Color Chart (Munsell System). Textural classification was performed according to the Unified Soil Classification System. Boring logs are found in Appendix A.

The rock core from CO1 was logged by Weston and Arthur D. Little geologists, photographed, and placed in wooden core boxes to be stored at the AMTL.

4.4 Sampling

Soil sampling for geological logging, chemical analysis (Table 5), and physical testing (Table 6) was done by Weston geologists supervised by Arthur D. Little personnel. Water sampling of the monitor wells was done by Arthur D. Little personnel. Details of the sampling and

decontamination methodologies are presented in Arthur D. Little's Sampling Plan. (Arthur D. Little, 1988)

4.4.1 Geological Soil Samples

Geological samples were taken every 5 feet, when possible, using a standard 2 inch 0.D. split spoon. A standard 140 pound weight was dropped 30 inches to advance the split spoon. Split spoons were decontaminated between use by brushing and rinsing with tap water. Samples were logged and placed in 2 inch diameter, clear glass jars, and stored at the AMTL. All geological samples and drill cuttings were monitored using an HNU PI-101 meter for volatile organic compounds and for radiation using a pancake Geiger-Muller probe and a NaI gamma detector.

4.4.2 Soil Samples for Chemical Analysis

Soil samples were taken for chemical analysis at predetermined depths in each hole for a set of predetermined analytes (Table 5). Samples were taken using standard 2 and 4 inch 0.D. stainless steel split spoons. Samples were placed in jars and vials supplied by Metatrace, (the analytical services contractor), labeled, sealed, and stored in ice in insulated coolers. Decontamination of the split spoon and associated sampling equipment consisted of:

- (a) non-phosphate detergent wash;
- (b) triple rinse with tap water;
- (c) rinse with pesticide-grade hexane;
- (d) rinse with deionized, distilled water;
- (e) wrap in aluminum foil.

As with the geological soil samples, the soil samples taken for chemical analysis were screened for volatile organic compounds using an HNU PI-101 meter and for radiation using a Geiger-Muller pancake probe and a NaI gamma detector.

A chain-of-custody form was completed and the samples shipped by Federal Express to Metatrace, Earth City, Missouri for analysis.

4.4.3 Soil Samples for Physical Analysis

Soil samples were taken for physical analysis at the intervals shown in Table 6. Samples were taken using a 2.875 inch I.D. Shelby tube in compressible soils and a 2 inch O.D. standard split spoon in incompressible soils. Shelby tube samples were sealed in the tube with paraffin. Samples taken with a split spoon were placed in 2 inch diameter clear glass bottles. Physical analyses were performed at Goldberg Zoino Associates, Inc., Newton, Massachusetts soil laboratory.

4.4.4 Water Samples for Chemical Analysis

Water samples were taken from each monitor well for chemical analysis. Prior to sampling the well, the air space was monitored for volatile organic compounds using an HNU PI-101 meter. A water level measurement was made using a Solinst (Model 101) electrical conductivity water level meter. To purge the well, five well volumes of water were removed using a Robin EY25W submersible or Meyer pump. Before each well volume of water was removed, pH, conductivity, and temperature were measured. Purge water was placed in 55 gallon drums and labeled for later disposal. Water samples were taken using a Teflon bailer and placed in bottles supplied by Metratace, preserved as necessary, sealed, labeled and stored in ice. Samples of water submitted for dissolved metal analysis were filtered using a 0.45 micron Sample-Pro FF8100 filter and preserved with HNO2. chain-of-custody form was completed and the samples shipped to Metatrace, Earth City, Missouri for analysis. Copies of these forms are found in Appendix I.

Teflon bailers were decontaminated between wells by the following procedure:

- (a) non-phosphatic detergent wash;
- (b) triple rinse with tap water;
- (c) 10% HNO₂ rinse;
- (d) triple rinse with tap water;
- (e) double rinse with pesticide-grade hexane;
- (f) rinse with deionized, distilled water;
- (g) wrap in aluminum foil.

Calibration techniques and frequencies for the pH-conductivity meter and thermometer are detailed in the Arthur D. Little, Inc., Sampling Plan.

4.5 Well Installation

Sixteen of 17 borings at AMTL were completed as monitor wells by GZA Drilling, Inc., under the supervision of Weston Geophysical Corporation and Arthur D. Little, Inc.

4.5.1 <u>Technique</u>

Wells were constructed of casings and screens consisting of 4 inch, flush-threaded schedule 40 Polyvinyl Chloride (PVC) pipe. The screened interval was constructed using 10 foot, 0.10 inch slotted PVC screen extending from 2 feet above to 8 feet below the water table, as observed at the time the hole was drilled.

The granular filter pack extended no more than 5 feet above the top of the screen. Five feet of bentonite pellets were placed above the granular pack. The remainder of the annular space was filled with bentonite grout to within 5 feet of ground surface. After the bentonite grout settled, the hole was sealed from surface to approximately 5 feet with concrete. The concrete had the following specifications:

- (a) maximum aggregate size of 3/4 inches;
- (b) comprehensive strength of 3000 psi at 28 days; and
- (c) six inch maximum slump.

Prior to installation, all well materials (casings, screen caps) were steam cleaned. All casing joints were threaded and no solvent, glues or thermal welding procedures were used to join well casing materials.

Wells were completed by cutting the 4 inch PVC casing off approximately 6 to 12 inches below grade, installing a 4 foot long, 6 5/8 inch diameter steel protective casing with locking cap over the PVC casing (about 3 inches below grade) and finishing with a 13 5/8 inch diameter gasketed manhole (1 inch above grade) set in cement (Figure 11). Sand was placed above the grout, below the concrete to drain any water that might enter the annular space between the PVC well casing and the steel protective casing.

Some wells (M01, M02, M05, M06, M10, M11, M13, and M14) were sufficiently shallow that the grouted interval was omitted. The surficial cement seal rests directly on the bentonite pellet seal in these wells. Details of individual well construction are documented on the well construction forms in Appendix B.

4.5.2 Materials

<u>PVC Casing and Screen</u>. Casing and screen used consisted of 4 irch flush threaded schedule 40 polyvinyl chloride (PVC) pipe conforming to the National Sanitation Foundation Standard 14 bearing a rating logo for potable water use. The screen was machine slotted 0.010 inch. All casing and screen were steam cleaned by the manufacturer and wrapped in plastic. The casing and screen were supplied by Diedrich Drilling Equipment, Inc., of LaPorte, Indiana.

<u>Granular Filter Pack</u>. The granular filter pack consists of silica sand (Mystic White Pool Filter Sand) supplied by U.S. Silica Company, Ledyard, Connecticut. The size distribution is shown in Figure 12.

<u>Bentonite</u>. Bentonite (Quik-Gel) supplied by NL Baroid/NL Industries was used in the grout formulation. It consists of finely ground sodium bentonite. Bentonite pellets (Bentonite PI Pellets 3/8 inch) supplied by Piezometer Research and Development, Bridgeport, Connecticut, were used as a seal above the sand pack.

FIGURE 11. WELL COMPLETION (MANHOLE-TYPE)

Bentonite Grout. Grout used in well construction consisted of 20 parts Portland cement (Type II or V), 1 part bentonite, and a maximum of 8 gallons of water per 94 pound bag of cement. Grout was placed in the annular space above the bentonite seal to within 5 feet of the ground surface by tremie pipe method.

<u>Drilling Water</u>. Water used during the drilling program was obtained from a fire hydrant at the AMTL. Water is supplied to the hydrant by the Massachusetts Water Resources Authority from the Norumbega, Weston, and Spot Pond Reservoirs. The water was sampled and analyzed for sulphate, chloride, metals, volatiles, and semivolatiles.

4.6 Well Development

All wells were developed no sooner than 48 hours after well construction but prior to seven days. The wells were developed by removing at least five well volumes based on the volume of water in the well casing and screen and the saturated well annulus assuming 30 percent porosity. In some situations, as M13, more than five volumes were removed to obtain clear water. Conductivity and pH were also monitored prior to, during and after development to document stabilization of these parameters. Pumping was done using a 4 inch Robin EY25W submersible pump or a Meyer surface pump with plastic hose. Development water was placed in 55 gallon drums, labeled, and stored for disposal. Well development was done by personnel from GZA Drilling, Inc., Weston Geophysical Corporation, Arthur D. Little, Inc., and EG&G Idaho, Inc. Details of well development for each well are documented on forms found in Appendix C.

4.7 Geophysical Surveying

Three geophysical surveys were conducted at the AMTL:

- (a) a ground penetrating radar survey to locate buried utilities at potential monitor well sites;
- (b) a refraction seismic survey to map depth to bedrock and provide information on stratigraphic correlation; and
- (c) a borehole geophysical survey in CO1 and CO3 to provide information on stratigraphic correlation.

The ground penetrating radar and seismic refraction surveys were performed by Weston Geophysical Corporation and the borehole geophysical surveys by Appalachian Coal Surveys, Pittsburgh, Pennsylvania, under the supervision of Weston Geophysical Corporation.

4.7.1 Ground Penetrating Radar Survey

A ground penetrating radar survey of the initially proposed monitor well and borehole locations at the AMTL was conducted to identify and locate buried utilities present, such as electrical conduits,

telephone conduits, and piping. It was not intended to provide any geological information. Ground penetrating radar is an electromagnetic survey technique that reveals a graphic cross-sectional view of layered material below the ground surface. It is an echo-ranging technique similar to the single-trace reflection method commonly used in marine bottom profiling in which reflective layers are traced by echo patterns generated in response to acoustic impulses. The two techniques differ in that the acoustic method uses audio frequency sound waves transmitted through a water medium to the material under investigation. The radar method transmits, directly to the surface, impulses of radio waves at frequencies up to a 1000 megahertz.

In a radar system, high-frequency impulses of radio energy are generated by the transmitter. A beam of these impulses is emitted by a special antenna placed in close proximity to the ground so that it couples electromagnetically to the surface material. Each impulse propagates downward through the ground surface and into the material below. At interfaces, part of the signal is reflected while part is transmitted still deeper to be reflected by other layers or isolated bodies. For each impulse transmitted, a string of reflected impulses is returned to the antenna in a time sequence proportional to the round-trip travel time to each reflector. After transmitting the outgoing pulse, the system instantly switches from the transmitter to the receiver in order to detect the echo signals. When operated in the field during data acquisition, a graphic recorder provides an immediate view of the data.

Ground penetrating radar surveys are carried out by pulling the antenna slowly along a pre-measured survey line. Radar impulses are transmitted synchronous with a swept-stylus type graphic recorder. The recorder stylus sweeps across the paper at a uniform speed and echo signals cause the paper to be darkened at points proportional to the total travel time to the reflector producing the echo. The recorder detects the presence of an echo whenever the signal level exceeds a preset threshold. The pattern of darkened regions on the paper marks the reflective horizons in the earth. The distance shown on the recorder paper to any reflector is proportional to its depth below the path of the antenna.

Accurate determination of the depth to any layer requires calibration of the radar system. The depth to an identified reflector such as a pipe, a barrel or a geologic feature, is the most direct and easiest method available for vertical scale calibration.

Depth of penetration in a given material is limited by attenuation of the signal. Attenuation is a function of dielectric loss and of electrical conductivity loss which, in a given material, will vary with the amount of water, dissolved salt, temperature, density, and frequency of the radar impulses. Penetration of up to 75 feet has been reported for water saturated sands in Massachusetts glacial sediments. Wet clays, however, will attenuate the signal within five

feet. It is important to note that in a layered material a single, highly reflective layer alone can limit penetration by preventing the propagation of energy past it. In this case, apparent loss of energy is caused by reflection rather than by dissipation.

4.7.2 Seismic Refraction Survey

The seismic refraction survey method is a means of determining the depths to a refracting horizon and the thickness of major seismic discontinuities overlying the high-velocity refracting horizon. seismic velocities measured by this technique can be used to calculate the mechanical properties of subsurface materials as well as for stratigraphic correlation. identification and material Interpretations are made from travel time curves showing the measurement of the time required for a compressional seismic wave to travel from the source (shot) point to each of a group of vibration sensitive devices (seismometers or geophones). The geophones are located at known intervals along the ground surface. Various seismic sources may be used, including a drop weight, an air gun, and small explosive charges.

Weston Geophysical Corp. used a seismic recording technique of continuous profiling and overlapping spreads. The seismic refraction equipment consisted of a Weston Geophysical trace amplifier, Model USA780, with a WesComp field computer system developed by Weston Geophysical and a recording oscillograph. In general, shots were located at each end and at the center of the seismic spread. A 1,000 pound drop hammer was used as a seismic energy source. Geophone spacings of 10 and 20 feet were used.

Continuous profiling was accomplished by having the end shot-point of one spread coincident with the end or intermediate position shot-point of the succeeding spread. The spread length used was determined by the required depth of penetration to the refracting horizon. It is generally possible to obtain adequate penetration when the depth to the refracting horizon is approximately one-third to one-quarter of the spread length.

The seismometer or geophone is in direct contact with the earth and converts the earth motion resulting from the shot energy into electric signals; a moving coil electromagnetic geophone is generally used. This type of detector consists of a magnet permanently attached to a spiked base which can be rigidly fixed to the earth's surface. Suspended within the magnet is a coil-wrapped mass. Relative motion between the magnet and coil produces an electric current with a voltage proportional to the particle velocity of the ground motion.

The electric current is carried by cable to the recording device which provides simultaneous monitoring of each of the individual geophones. The operator can amplify and filter the seismic signals to minimize background interference. For each shot the seismic signals detected by a series of geophones are recorded on either photographic paper or

magnetic tape, depending on job requirements. Included on each shot record is a "time break" representing the instant at which the shot was detonated.

The elastic wave measured in the seismic refraction method, the "P" or compressional wave, is the first arrival of energy from the source at the detector. This elastic wave travels from the energy source in a path causing adjacent solid particles to oscillate in the direction of wave propagation. At small distances between source and detector, the first arriving waves will be direct waves that travel near the ground surface through the lower velocity material. At greater distance, the first arrival at the detector will be a refracted wave that has taken an indirect path through the two layers. The refracted wave will arrive before the direct wave at a greater distance along the spread because the time gained in travel through the higher-speed material compensates for the longer path. Depth computations are based on the ratio of the layer velocities and the horizontal distance from the energy source to the point at which the refracted wave overtakes the direct wave.

Generally, the interpretation is by one or more of several methods such as ray-tracing, wave front methods, delay times, critical distances (W. M. Telford, et al., 1976). In addition, either a forward or inverse interpretation was performed using Weston's proprietary software. Since successful refraction interpretation is based on experience, all interpretation of refraction data were performed or thoroughly reviewed by a senior staff geophysicist.

4.7.3 Borehole Survey

Methods and Equipment

The boreholes at AMTL were logged by Appalachian Coal Surveys of Pittsburgh, Pennsylvania. Their equipment consisted of a truck mounted borehole logging system manufactured by Well Reconnaissance Inc., (now MLS, Inc.) of Fort Worth, Texas. All tools were less than 1-1/2 inches in diameter and enclosed in stainless steel housings. The logging cable used was 3/16 inch diameter, stainless steel, wire wrapped, four conductor and chemically stable. The following tests were run when possible:

- (a) caliper
- (b) natural gamma
- (c) high resolution, short-spaced gamma-gamma density
- (d) long-spaced gamma-gamma density
- (e) neutron
- (f) fluid conductivity
- (g) spontaneous potential
- (h) temperature
- (i) wall resistivity

Resolution for each method is given in Table 7. Copies of the borehole logs are found in Appendix F.

The primary assumption made in borehole geophysical logging is that the measured properties are representative of the formation and that they are made in undisturbed material. This assumption is not always valid due to the fact that the radius of investigation (depth of penetration into the formation) of the tools may vary with the physical properties of the formation. However, good correlation was found between geophysical logs, sample logs, and well completion diagrams at the AMTL site.

Caliper

The caliper log uses a three-arm caliper to measure variations in hole diameter. It is only run in an uncased hole.

Natural Gamma

The natural gamma log uses a gamma ray detector to measure the gamma energies emitted by naturally occurring uranium, thorium and potassium (K^{40}) . Generally, a gamma detector sensitive only to the narrow ban of energy (1.46 Mev for K^{40}) is used to distinguish potassium which is a common constituent of illitic-clay minerals, alkali feldspars, and micas. It is used to correlate shales and clay-rich sediments.

Gamma-Gamma Density

The gamma-gamma density logs measure in situ density using two sondes. The bottom sonde uses a concentrated source of monoenergetic gamma rays (Am 241 and Ra 226). The upper sonde, approximately 18 inches above the source uses a Geiger or scintillation detector. The source is shielded from the detector which only detects gamma rays which have travelled through the rock. Because of interaction with the rock, the detected level of gamma intensity is exponentially related to rock density. For a short source-detector separation, adjacent beds and bed thickness have little effect. However, the thickness and density of drilling muds or bentonite will affect the short-spaced log. Greater source-detector separation can be used to overcome mud and bentonite thicknesses.

Neutron

Neutron logs measure porosity by determining the amount of hydrogen, and therefore fluid, filling formational pore spaces. Neutrons emitted from an Am-Be source collide with hydrogen nuclei and are slowed to thermal energy. They may then be captured by other nuclei which emit capture gamma rays. Either capture gamma rays or thermal neutrons may be detected and measured. In large diameter holes with significant mud build-up (or annular bentonite in a well) the results may be less accurate.

TABLE 7. BOREHOLE GEOPHYSICAL LOGGING

<u>Technique</u>	Primary Area of Investigation	Vertical <u>Resolution (ft)</u>	Source
Caliper	В	Hole Diameter <.25 inch	Passive
Natural Gamma	F	1.5	Passive
Gamma-Gamma .	С	0.25	250 mCi Am241

Fluid Conductivity	В	N/A	Passive
Spontaneous Potential	F	0.5	Passive
Temperature	В	N/A	Passive
Wall Resistance	В	0.25	DC Voltage

F = Formation

Source: Weston Geophysical Corporation

B = Borehold

C = Well Construction

Fluid Conductivity

The fluid conductivity of a formation can be determined by measuring the conductivity of the pore fluid which contains dissolved salts which disassociate into cations and anions. The sonde uses a direct current voltage applied between two electrodes and measures the potential between two potential electrodes. The accuracy of the method decreases when the formations adjacent to the hole are infiltrated by drilling muds or bentonite.

Spontaneous Potential

The spontaneous or self-potential method measures the potential across a lithological contact. For instance, a clay or shale is permeable to Na cations but not to Cl anions. Consequently, a potential develops at the boundary of a clay (shale) and sand as Na cations pass into the shale and Cl anions increase in concentration in the sand. Instrumentation consists of a potentiometer connected to a downhole and surface electrode. It can only be used in uncased holes.

<u>Temperature</u>

Temperature of the well water is recorded using a thermocouple.

Wall Resistivity

Wall resistivity is measured using a sonde with electrodes that are in continuous contact with the wall. It provides some correlation with porosity since it is sensitive to the thickness of drilling muds and bentonite, which cannot infiltrate impermeable units. It can only be used in uncased holes.

4.8 <u>Topographic Surveying</u>

The surface elevation and coordinates of all monitor wells were determined by Design State Survey, Medford, Massachusetts. Coordinates were measured in the Massachusetts State Coordinate (Mainland) System to 1/100 of a foot. Elevations were measured relative to the National Geodetic Vertical Datum of 1929 to 1/100 of a foot. All data exceeds the contract specifications of horizontal control of \pm 3 feet and vertical control of \pm 0.05 feet. The survey instruments used were a Wild T-1000 transit and a Wild DM-1000 distance measuring device.

4.9 Aquifer Tests

Tests to determine in situ hydraulic conductivity were conducted in all borings. In CO1, the bedrock portion of the hole was isolated with an inflatable packer and a pressure test was conducted. In all other holes, a metal slug was used to conduct falling and rising head tests. All of the tests were designed and supervised by hydrologists from Weston Geophysical Corporation. Field data and

plots of recovery versus time for each well are found in Appendix E.

4.9.1 Packer Test in CO1

A single packer (St. Lawrence) test was used to evaluate the hydraulic conductivity of the Cambridge Argillite penetrated by hole CO1. The packer consisted of 10 foot long 15/16 inch interior diameter pipe sections leading through an expandable rubber bladder (packer). The packer sealed off the section of the corehole to be tested and was inflated with compressed air supplied from the surface. The pipe was perforated below the packer to allow water supplied from the surface to flow into the borehole and the surrounding formation. The equipment layout is shown schematically in Figure 13.

After checking the accuracy of the water flow meter and water pressure gauge and measuring the water depth in the borehole, the packer and water pipe were placed in the hole. The packer was inflated at 68 feet, 7 feet below the bedrock surface, to isolate the bottom of the hole from any weathered fractured rock at the top of bedrock which would allow hydraulic communication with the overlying glacial till. Tests were conducted at 10, 21, 35, and 51 p.s.i. During each test, the change in water flow was recorded every 30 seconds for 5 minutes. After conducting the four tests, the hydraulic conductivity was calculated.

Hydraulic conductivity was calculated from the formula given in <u>Earth Manual</u>, page 576 (United States Bureau of Reclamation, 1974):

$$K = \frac{O}{2\pi LH} \times \ln (L/R)$$

where K = hydraulic conductivity (gallons/minute/ft²)

Q = constant rate of flow into the hole (gallons/minute)

L = length of the hole tested (feet)

h = differential head of water over distance from water table to water swivel (feet)

r = radius of hole (feet)

4.9.2 Monitor Well Slug Tests

A falling head and rising head slug test technique was used to evaluate in situ hydraulic conductivity. A solid 3 inch diameter PVC slug was used to displace the water in the well. In all but three wells a 5 foot long slug was used. In wells MO3, MO4, and M12, a $1\frac{1}{2}$ foot long slug was used. This smaller slug was needed due to the smaller water column present in the wells.

After measuring the water level in the well, a transducer was lowered into the well to within a few inches of the base of the screen. All the pertinent test parameters were entered into a Hermit Environmental Data Logger Model SE1000B. At the start of the test, the slug was instantaneously lowered into the well until it was completely

submerged. The height of the water column (above the initial reference level) was recorded on a logarithmic time scale by the Hermit as the water level recovered to its initial position.

After the water level stabilized in the well, a rising head test was conducted in a similar manner to the falling head test. The slug was instantaneous withdrawn from the well and the subsequent rise of water with time was recorded by the Hermit. After completing the falling and rising head test on each well, a hard copy of the recorded data was printed out for a quality review.

The method of Hvorslev (Freeze and Cherry, 1979, pp. 339-342) was used to calculate the hydraulic conductivities from the raw data collected. The maximum displacement of water, and subsequent recoveries relative to the maximum displacement, were plotted versus time on semi-logarithmic paper (Appendix E). From the resulting best-fit line, the time (T) for a relative displacement of 0.37 was calculated from the plot and entered into Hvorslev's formula:

$$K = r^2 \frac{\ln (L/r)}{2 LT_0}$$

where r = radius of well

L = height of water in borehole and well

The hydraulic conductivities calculated from rising head tests are generally more accurate than falling head tests with a partially penetrating well screen. However, the falling head tests can be used to check the accuracy of the rising head tests. That is, if the test results agree or the falling head test gives a slightly higher hydraulic conductivity, then the results are more likely to be accurate.

4.10 Physical Tests

Samples were taken for physical testing by the Weston Geophysical geologists during drilling. In compressible soils, a 2.875 inch I.D. Shelby tube sample was taken. In incompressible soils, a sample was taken using a conventional 2 inch O.D. split spoon. Shelby tube samples were capped and sealed with paraffin. Split spoon samples were placed in 2 inch clear glass jars. All samples were delivered to the Goldberg Zoino & Associates, Inc., Soils Laboratory in Newton, Massachusetts for testing. Data summaries and grain size plots are found in Appendix G.

4.10.1 Atterberg Limits

Atterberg limits (liquid limit and plastic limit) were determined for all samples except for MO3 and MO4 which were gravels and, therefore, too coarse grained for testing. Testing specifications are given in ASTM Volume 04.08, Procedure D4318-84.

The liquid limit is measured in a standard liquid limit device. The device essentially consists of a cup in which soil at various moisture contents is placed, the soil is grooved with a standard tool and the cup struck by a cam. The liquid limit is determined when the groove closes to a specified width at 25 blows. The soil is weighed, oven dried, and weighed again. The percentage of water by weight to dry weight of soil is the liquid limit.

The plastic limit is determined by rolling the soil into a 1/8 inch string. When the soil string begins to crumble (plastic limit), it is weighed, oven dried, and weighed again. The percentage of water by weight to dry weight of soil is the plastic limit. The plasticity index is the difference between the liquid limit and the plastic limit.

4.10.2 Specific Gravity

Specific gravity is determined by comparing the soil's weight in air against its weight loss in water. Testing specifications are given in ASTM Volume 04.08, Procedure D854-83.

4.10.3 Porosity

Porosity was calculated from determination of dry density and specific gravity in the following manner:

$$P = ((1 - v_s)/v_s) \times 100$$

P = porosity

 $1-v_s$ = volume of pore space

 v_s = volume of solid = dry unit wt/spec. gravity x unit wt water

4.10.4 Permeability

Permeability tests were performed on samples to reconstitute specified densities approximately equivalent to 95 percent of modified Proctor (ASTM Volume 04.08, Procedure D1557-78) at about 2 percent wet of optimum water content.

Reconstituted test specimens were prepared in a manner similar to that described in "Special Procedures for Testing of Soil and Rock for Engineering Purposes" STP 479, ASTM 5th Edition, pages 101-103. Each specimen was reconstituted in 2.0 inch diameter by 4.0 inch long sample formers. A specific amount of soil at the appropriate water content was weighed in five equal portions. Each portion was tamped by means of a mechanical tamping foot to a specified height in the mold. After five layers were compacted, the sample was weighed, measured, and its unit weight verified. After verification of the unit weight, the test sample was placed on a previously evacuated, modified triaxial cell base and porous stone. A membrane was added and the sample sealed top and bottom by '0' rings.

Samples were back pressured under a small effective stress to create complete saturation of the sample. When the desired saturation was achieved, the samples were attached to the permeability apparatus and tested in accordance with procedures described in the Army Corps of Engineers Manual EM 1110-2-1906, Appendix VII, "Falling Head Permeability Tests with Back Pressure." Records of head change versus time were recorded for the test with the permeability value reported being the average of several consistent values obtained during the test.

4.10.5 Sieve Size Analysis

When both sieve and hydrometer analyses were required, a combined mechanical analysis was performed. This procedure is similar to ASTM Volume 04.08, Procedure D2217.66 (wet preparation of soil sample for grain-size analysis and determination of soil constants).

A representative portion of the minus No. 4 material was mixed with water so as to form a thin homogeneous slurry. The fines suspended in this slurry were then decanted into an empty hydrometer jar, and the mixing-decanting process repeated until most of the fines had been removed. Coarser fractions remaining after the decantation were then oven dried and sieved through a nest of screens (Nos. 10, 20, 40, 50, 100, and 200). Any material passing the No. 200 screen was added to the hydrometer jar containing the finer fraction. Hydrometer analysis of these fines was performed in the conventional manner.

5.0 DISCUSSION OF RESULTS

The purpose of this program was to provide a geologic and hydrologic characterization of the AMTL site which could be used as a framework to predict and explain the direction and rate of transport and extent of any contamination which might be found. Geologic characterization was achieved through careful logging of boreholes and coreholes, borehole geophysics, and a refraction seismic survey. Hydrologic characterization was achieved by physical characterization and testing of soil samples, measurement of the water level, and performing packed pressure tests and slug (falling and rising head) tests. From these measurements and observations, the following hydraulic parameters were calculated: gradient, flow direction, hydraulic conductivity, flow velocity, and flow rate.

While soil and groundwater samples were obtained as part of this program, chemical analysis of these samples and interpretation of contaminant transport and significance were not part of this program.

5.1 Geologic Characterization

Details of the geology at the AMTL have already been discussed in Section 3.0 Site Geology. Therefore, only a brief summary of the stratigraphic sequence is therefore provided here. Bedrock at the site consists of the Cambridge Argillite, a dense finely laminated siltstone consisting of bluish gray silt to clay beds with interbedded lighter colored, very fine to fine-grained, sandy beds. Most fractures are parallel to bedding, but other fracture orientations exist (fewer than four per foot). The siltstone is overlain by a basal, bouldery till with a gray green silt-rich sandy to gravelly matrix. fairly cohesive and dense. Laying on top of the till is a silty sand found across the site which is composed of moderately well sorted, very fine to fine-grained sand with a clayey-silty matrix. commonly laminated and locally becomes very silt/clay rich. Overlying the silty sand is a texturally variable layer of medium to coarsegrained sand and gravel which is not found over the entire site. It was not found in the northwest corner of the facility and it grades from a medium to coarse-grained sand to a gravelly sand eastward. This coarser unit over the silty sand commonly contains the first trace of water. The coarser sand/gravel layer is generally overlain by fill of disturbed gravels, commonly with exotic debris (concrete, brick, ceramic, etc.).

Additional geological information can be obtained from interpretation of the seismic refraction survey. The locations of the lines were shown in Figure 7 and the actual interpretative profiles in Figure 8. Profile 1 is characterized by four distinct seismic horizons. A material with velocities ranging from 1,000 to 1,800 feet/sec is seen from ground surface to a depth of 4 feet. These velocities are typical for fill material. This layer is underlain by a zone with a velocity of approximately 2,300 feet/sec, indicative of an

unconsolidated sediment. Included in this sequence is a water saturated zone at depths of 16 to 20 feet (from west to east, respectively). Unconsolidated, water saturated materials are characterized by seismic velocities of 5,000 feet/sec. Bedrock (siltstone) exhibits velocities of approximately 12,000 feet/sec. The bedrock surface varies in depth from 44 to 110 feet (Figure 8). Boring information obtained adjacent to Profile 1 indicates a thin, 6 foot basal till overlies the bedrock. This layer is not seen by the seismic method on Profile 1 because it is too thin to contribute significantly to the velocity plot.

Profile 2 is similar to Profile 1. Again, there are four distinct velocity zones. Between 14+00 and 23+00, the 1,000 to 1,800 feet/sec (fill) material is substantially thicker at 14 to 18 feet. The second horizon (unconsolidated sediments) appears to contain a facies change at approximately 24+50. From 14+00 to 24+50, the velocities are approximately 2,500 feet/sec which are indicative of a predominantly sandy environment. From 24+50 to 30+00, the sediment has a velocity of 3,000 to 3,500 feet/sec and is suggestive of a clay rich material. The water table is dipping slightly from north to south, towards the Charles River. Bedrock is relatively deep along the entire length of Profile 2. It varies from 85 to 115 feet and is characterized by a velocity of 11,000 feet/sec. The slightly lower velocity in the siltstone for Profile 2 (compared to Profile 1) can be attributed to the orientation of the survey line to the strike of the siltstone. Profile 1 is probably oriented parallel to the direction of the strike with Profile 2 oriented at some angle to strike. Profile 3 is characterized by a three layer seismic profile. A top layer of 1,200 to 1,900 feet/sec material is indicative of organic matter and fill. This layer extends to a depth of 8 to 10 feet. Water saturated material (5,000 feet/sec) is then observed to depths of 60-72 feet, the presumed top of the bedrock.

Borehole geophysical surveys were run in holes (CO1 and CO3). The original intent of the borehole surveys was to use logging techniques in deep holes cored into bedrock to determine physical properties of the unconsolidated glacial sediments and bedrock to provide stratigraphic correlation.

Hole CO1 was drilled to a total depth of 78 feet, the lower 16.5 feet cored in bedrock. The steel casing extended to bedrock at 61 feet. Because of the steel casing, most information was obtained in the bedrock interval only. Caliper, natural gamma, short and long spaced gamma density, neutron, resistivity, spontaneous potential, temperature, and fluid conductivity logs were run.

The caliper log was only run in the open hole (59-75 feet) and indicated a void at 61-62 feet, probably a washout at the bedrock surface created during drilling. In the bedrock interval, the natural gamma log ranged from 50-60 cps (approximately 60% clay) relative to an average of 15 cps for the unconsolidated glacial sediments confirming the high potassium (clay) content of the bedrock. The

slight increase from 12-13 cps (approximately 25% clay) below 25 feet to 17-18 cps (approximately 35% clay) below 25 feet indicates increasing clay content at depth in the glacial sediments. Rapidly increasing values below 57 feet (>40-50 cps) indicate the clay rich nature of the basal till.

Short spaced density measurements give a density of approximately $2.2 \, \text{g/cm}^3$ slightly below average $(2.4 \, \text{g/cm}^3)$ for a wet shale. The long spaced density measurements show relative density difference breaks that seem to correlate well with lithology:

- (a) 0-25 feet silty sand
- (b) 25-45 feet sand
- (c) 45-50 feet clayey sand
- (d) >56 feet basal till

The spontaneous potential log shows a notable negative deflection for the siltstone. The neutron log shows discontinuities at approximately 25 feet, 52 feet, and 62 feet. The lower values in the interval 25-52 feet and at 62 feet reflect the higher porosity of the sand and a void respectively. Porosity of the silty sand and the siltstone appear comparable which is not likely. The till (56-61 feet) exhibits a porosity intermediate to the silty sand and sand.

Temperature and fluid conductivity both show gradual decreases as depth increases from about 28 feet (the water level). Temperature decreases from 55°F to 53°F and conductivity from approximately 25 to 15 ohm -m.

Hole CO3 was bored to total depth of 37.5 feet terminating in basal till. It was cased with 4 inch PVC and screened from 24.6 to 34.6 feet. Logs included natural gamma short and long spaced gamma density, neutron, temperature, and conductivity.

The natural gamma log shows a broad peak centered at approximately 20 feet which expresses the presence of the bentonite seal from 17 to 22 feet. The low centered at 10 feet is an expression of the sandy peat from 8 to 15 feet. The long spaced gamma density correlates very generally with stratigraphy: a general low with several narrow peaks correlating with the silty sand (16-29 feet); and a broad peak correlating with a gravel (30-33 feet). Temperature varied from 56 to 58°F and conductivity was approximately constant at 10 ohm -m.

5.2 Hydrological Characterization

Details of the hydrology at the AMTL have already been discussed in Section 3.0, Site Geology. Only a brief summary of the hydraulic regime (Table 8) is presented here. Run-off of surface water is to the south toward the Charles River. Because of the extensive presence of structures and paving, most surface run-off is captured by the storm drain system and discharged to the river.

5-10 ft bre 7 1. Born

TABLE 8. HYDRAULIC PARAMETERS

1. Gradient (i)

- a. West portion: 0.025 to south.
- b. East central portion: 0.030 to southeast, swings to 0.005 to south.
 6.0034

2. Hydraulic Conductivity (k)

a. Silty sand:

$$6.4 \times 10^{-3}$$
 cm/sec (average)
7.06 x 10^{-4} - 1.30 x 10^{-2} cm/sec (range).

b. Medium-coarse sandy gravel:

$$2.7 \times 10^{-2}$$
 cm/sec (average)
 4.24×10^{-3} - 3.30×10^{-2} cm/sec (range).

c. Siltstone:

$$4.1 \times 10^{-7}$$
 cm/sec (average)
 1.72×10^{-7} - 8.88×10^{-7} cm/sec (range).

3. Flow Rate (0)

a. $0.016 \text{ m}^3/\text{sec} (98 \text{ gpm})$.

4. Flow Velocity (v)

- a. Site average: 4.5×10^{-4} cm/sec (142 m/year).
- b. Southeast portion: 4.5×10^{-5} cm/sec (14.2 m/year).

Using K & (2.7×1/2) (0.00364) = 2.17×10-4 (1/2) = 67.3 Mygen for Mid-Soul

Characterization of the groundwater hydraulics are based on 17 borings, 16 of which were completed as monitoring wells. Water level data, summarized in Table 5 and graphically interpreted in Figure 10 show groundwater flow is generally to the south toward the river. In the northeast corner, flow is to the southeast and then swings around to the south. The gradient averages 0.03 across the site, but in the southeast corner, it decreases to 0.003.

In situ hydraulic conductivities (k) were determined using falling and rising head tests. In the silty sand, which seems to be the dominant water-bearing unit over all of the site, k ranges from 7.06×10^{-4} to 1.30×10^{-2} cm/sec and averages 6.4×10^{-3} cm/sec. The medium to coarse sandy gravel has a range of k from 4.24×10^{-3} to 3.30×10^{-2} cm/sec with an average of 2.7×10^{-2} cm/sec. The siltstone (bedrock Cambridge Argillite) has an average k of 4.1×10^{-7} cm/sec, and is expected to effectively serve as a hydraulic barrier to the glacial sediment-hosted aquifer. We did not determine k for the basal till. Values reported in the literature for the Boston area (Hatheway, 1982) range from 10^{-5} to 10^{-9} cm/sec.

To calculate a representative flow rate (Q), a cross sectional area perpendicular to the gradient extending from near MO1, then east to near MO3, and finally northeast to near MO8, approximately 2,000 feet was selected. The aquifer thickness (H) ranged from approximately 40 feet at the west to 47 feet at the east. We assumed that the siltstone provided an effective basal confining layer for the aquifer. The cross sectional flow area was estimated at 8080 m². Review of the drill logs and cross section M10-M07 (Figure 5) suggests that the silty sand is the predominate hydrologic unit. Review of the seismic Profile 1 (Figure 8) indicates most of the saturated zone is within a fairly uniform material, based on consistent seismic velocities of 5,000 feet/sec. Based on the preceding arguments, a hydraulic conductivity of 6.4 x 10^{-3} cm/sec, the average for the silty sand, was used. An average gradient (i) of 0.03 was selected. The flow rate, Q, can now be calculated:

Q = k i A

- 0.016 m³/sec (98 gpm) 2530 m

- 504576 m³/year (51,508,800 gal/year) 13320分のタ

Representative average linear velocities can be calculated by:

v = ki/n

Using an average porosity (n) of 0.43 for the silty sand, gradients (i) of 0.03 and 0.003 and the average hydraulic conductivity (k) for the silty sand, calculated flow velocities range from $1.7 \times 10^{-4} \times 10^{-4} \times 10^{-4} \times 10^{-5} \times 10^{-5} \times 10^{-5} \times 10^{-4} \times 10^{-4}$

7!

These velocity estimates represent the rate at which the centroid of a contaminant plume would move in the absence of attenuating mechanisms such as adsorption by soil or degradation. Dispersion would cause the leading edge of a plume to travel faster, and the trailing edge to travel slower than the centroid. For example, the centroid of a plume could travel the 183 m from CO2 to the southern site perimeter in approximately 18 years, using a velocity of 3.2×10^{-5} m/sec (10 m/year). Dispersion would decrease the time at which contaminants originating near CO2 would reach the southern boundary and would also increase the time period over which contaminants might be detectable at the southern boundary.

Attenuation by soil adsorption or degradation, on the other hand, could potentially increase the travel time by an order of magnitude or more, depending on both the soil and contaminant properties.

Given the information obtained from the 17 borings and 16 monitor wells, the hydrologic regime at the AMTL appears relatively simple. The surficial aquifer is unconfined and is bounded by the underlying siltstone bedrock and flows south toward the river. Variation in the textural composition of the unconsolidated glacial sediments accounts for minor variations in gradient, hydraulic conductivity and flow velocity.

6.0 RECOMMENDATIONS

Our recommendations can be put in two general categories: general and site specific. General recommendations are based on our extensive experience in drilling thick sequences of unconsolidated glacial sediments. Site specific recommendations are based on our experience at the AMTL.

6.1 General

6.1.1 Well Finish

We recommend that all permanent monitoring wells constructed in an urban environment, or even a suburban environment be completed per our design of Figure 11. This type of well finish offers

- (a) two levels of security (bolted manhole and padlocked steel casing);
- (b) a flush finish that does not present a safety hazard;
- (c) a flush finish that is aesthetic and does not detract from its surroundings, particularly important at the AMTL because of the historic nature of the buildings;
- (d) four levels of protection for the well, gasketed manhole, steel casing security cap, drain at base of steel casing and a slip cover on the four inch PVC well casing.

6.1.2 Bedrock Holes

A common practice in drilling at a location where there is little to no information on depth to bedrock, depth to water table and the nature of the stratigraghy, is to attempt to drill one or more deep holes to bedrock, or into bedrock, to log and sample stratigraghy and to complete the hole s a monitor well. It is commonly perceived that this is a most economical way to get the maximum information, when in fact, it is often not.

It is generally more expedient and easier to drill at least one deep hole. Using a rotary bit and steel casing and sampling with a split spoon every 10 feet until bedrock is encountered, the hole can be rapidly advanced. Cuttings can be examined for general trends in geology although there is separation of fine particles.

When bedrock is encountered, reduction to the appropriate size diamond core barrel is required to get continuous core samples. If core samples are not required, the chips from rotary bit can be logged. We would recommend a packer test in competent bedrock to measure in situ hydraulic conductivity and determine if the bedrock serves as a hydraulic barrier to the aquifer in the overlying unconsolidated sediments.

Since the rotary drilling technique may not offer the same degree of security in preventing cross contamination within the hole, it is not recommended that soil samples for chemical analysis be taken. Installation of a monitor well may not be prudent. It would probably be best to bore an adjacent hole using hollow stem augers to a predetermined depth, collect soil samples for chemical analysis, and complete as a monitor well.

6.1.3 Ground Penetrating Radar Surveys

In an urban area like the setting for the AMTL, it is recommended that utility clearances by the gas, electric, and telephone companies and the installation facility people be followed by a ground penetrating radar survey to verify the accuracy of "known" locations and to search for forgotten utilities.

6.1.4 Seismic Refraction Surveys

The use of seismic refraction surveys to determine depth to bedrock, general stratigraphic units and whether or not these units are saturated is an excellent idea. The survey is very cost effective for the information obtained and can generally be run in urban environments.

6.2 Site Specific

6.2.1 Borehole Geophysical Surveys

Borehole geophysical surveys were run in holes CO1 and CO3 at the AMTL. Neither hole was very deep, 78 feet and 37.5 feet respectively. CO1 has to be logged with 28 feet of 10 inch hollow stem auger, 56 feet of 8 inch steel casing and 61 feet of 4 inch steel casing which created some shielding" for the borehole tools. Most information obtained from the borehole logs was redundant with that obtained from geological logging, and we do not recommend running borehole surveys in a similar situation.

6.2.2 Additional Drilling

While the interpretation of analytical results is not in the scope of the Arthur D. Little, Inc. contract, we know that CO2 is at least moderately contaminated by the benzene-xylene-toluene group. Additional monitor wells are recommended both up and downgradient to attempt to identify the potential source area and the geometry of the contaminant plume. If, in addition to the light fraction, a heavy fraction is discovered, such as chlorinated solvents, monitor wells testing various levels in the aquifer are recommended. And finally, to assist in an initial assessment of applicable technology for remediation, a series of pump tests should be conducted to determine appropriate groundwater extraction rates.

Example Packer Test Calculation

Hydraulic Conductivity = K

$$K = \frac{Q}{2\pi LH} \times \frac{ln}{R}$$

Test #1

Q - 0.36 gallons/minute because 1.6 gallons (1049.6 - 1048.0) were added in 4.5 minutes.

So

L = 10 feet (length of hole tested)

H = H (gravity) + H (pressure)

H (gravity) = feet from water table to water swivel = 31.13 feet

H (pressure) = average gauge pressure (feet)

 $= 2.31 \times 12.3 \text{ psi} = 28.41 \text{ feet}$

So H = 31.13 feet + 28.41 feet = 59.54 feet

R = 1.875 inches = 0.157 feet

$$\frac{0.36 \text{ GPM}}{2\pi(10 \text{ ft.})(59.54 \text{ ft.})}$$
 x ln $\left(\frac{10 \text{ feet}}{0.157 \text{ feet}}\right)$ = 4.00 x 10⁻⁴ Gpm/ft² = 8.88 x 10⁻⁷ cm/sec
